Abstract

Sedimentation processes are fundamental to solids / liquid separation in water and wastewater treatment, and therefore a robust understanding of the settlement characteristics of mass fractal aggregates (flocs) formed in the flocculation stage is fundamental to optimized settlement tank design and operation. However, the use of settling as a technique to determine aggregates' traits is limited by current understanding of permeability. In this paper, we combine experimental and numerical approach to assess settling velocities of fractal aggregates. Using a non-intrusive in situ digital image-based method, three and two-dimensional fractal dimensions were calculated for kaolin-based flocs. By considering shape and fractal dimension, the porosity, density and settling velocities of the flocs were calculated individually, and settling velocities compared to those of spheres of the same density using Stokes' law.

Shape analysis shows that the settling velocities for fractal aggregates may be greater or less than those for perfect spheres. For example, fractal aggregates with floc fractal dimension, $D_f = 2.61$, floc size, $d_f > 320$ μm and $d_p = 7.5$ μm settle with lower velocities than those predicted by Stokes' law; whilst, for $D_f = 2.33$, all aggregates of $d_f > 70$ μm and $d_p = 7.5$ μm settled below the velocity calculated by Stokes' law for spheres. Conversely, fractal settling velocities were higher than spheres for all range of sizes, when D_f of 2.83 was simulated. The ratio of fractal aggregate to sphere settling velocity (the former being obtained from fractal porosity and density considerations), varied from 0.16 to 4.11 for aggregates in the range of 10 and 1000 μm, primary particle size of 7.5 μm and a three-dimensional fractal dimension between 2.33 and 2.83. However, the ratio decreases to the range of 0.04 to 2.92, when primary particle size changes to 1.0 μm for the same fractal dimensions.

43   Using the floc analysis technique developed here, the results demonstrate the difference in

44   settlement behaviour between the approach developed here and the traditional Stokes' law

45   approach using solid spheres. The technique and results demonstrate the improvements in

46   understanding, and hence value to be derived from an analysis based on fractal, rather than

47   Euclidean, geometry when considering flocculation and subsequent clarification performance.

48   **Keywords:** flocculation, fractal dimension, settling velocity, porosity, density

49

50   **Introduction**

51   Coagulation and flocculation are critical steps in drinking water treatment. During coagulation, a

52   coagulant (e.g. aluminium sulphate) is added to the water to neutralize the negatively charged

53   suspended particles, following which shear-induced interactions generated by slow mixing in a

54   flocculator cause their aggregation into mass fractal aggregates (flocs). Clarification processes in

55   water treatment are often based on sedimentation of flocs. In order to optimise sedimentation, it is

56   important to gain a fundamental understanding of floc settling behaviour. Traditional approaches

57   have used Stokes' law with its inherent assumptions of solid, spherical particles. Flocs are clearly

58   far more complex in structure and behaviour and, therefore, it is important that the impacts of these

59   features of flocs are understood in order that their settling behaviour can be assessed and so

60   predicted with accuracy.

61

62   Floc aggregation is a dynamic process where mass, surface area, number, and morphology change

63   as functions of the shear stress and time. Furthermore, whilst aggregates may have the same size,

64   they may exhibit different structures due to different particle arrangements during aggregation.

65   The variations in mass, surface area and concentration substantially affect floc behaviour,

66   particularly with regard to collision and to aggregation efficiency (Vahedi & Gorczyca 2012).

67

68   Therefore, the irregular shape and porous structure of fractal aggregates may oppose the predicted

69   settling rate using solid spheres. These traits may affect aggregates density and porosity, and so the

70   drag forces on floc surface, making velocities (and hydraulic loading rates) slower than the ones

71   predicted by Stokes' law (Chakraborti and Kaur, 2014; Vahedi and Gorczyca, 2012). This may

72   potentially influences on the predicted clarification efficiency of settling units, resulting in quite

73   more solids dragged out from the tank into the subsequent filters, which may not be designed for

74   such extra load. Hence, the correct prediction of aggregates settling rates is crucial for the accurate

75   design of sedimentation tanks and subsequent filters in a full-scale water treatment plant.

76

77   Fractal geometry has been extensively used to characterise non-uniform objects and its application

78   on sedimentation will be described below, after a brief description of its main characteristic.

79

80   **Fractal geometry**

81   Fractals may be described as objects that demonstrate self-similarity (i.e. the existence of the same

82   pattern irrespective of viewing magnification). They can be expressed via a power law relationship

83   comprising two variables, and characterised by non-integer fractal dimensions, as shown in

84   Equation 1 to 3.

85    $$A \propto L^{D_f} \tag{1}$$

86   and:

87    $$V \propto A^{D_f} \tag{2}$$

4

88   where *V*, *A* and *L* refer to fractal volume, area and length respectively, whilst D_f is the floc fractal

89   dimension.

90   In the case of flocs:

91    $$M \propto L^{D_f} \tag{3}$$

92   where *M* refers to floc mass.

93   Gregory (2009) described flocs as mass fractal objects and found that their fractal structure has

94   important practical implications for floc density. Indeed, several factors affect flocs' fractal

95   structure, including mixer device (Logan & Kilps 1995) and coagulation (Xu *et al.* 2010, 2011), as

96   floc strength is a function of the formation process (He *et al.* 2012). Gregory (2009) found that

97   aggregates formed by perikinetic flocculation display lower fractal dimension than those formed

98   during orthokinetic flocculation, whilst aggregates formed during sweep coagulation are of larger

99   size and fractal dimension compared with those formed during charge neutralization (Li *et al.* 2006,

100   Kim *et al.* 2001).

101   Fractal aggregates, when densely compacted, are close to Euclidean objects and so have a large

102   fractal dimension ($D_f \sim 2$, for two-dimensional objects), whereas smaller fractal dimensions result

103   from highly branched structures. It is believed that these more compact aggregates, rather than

104   those exhibiting large overall size, exhibit enhanced performance during sedimentation given that

105   the floc settling velocity depends on the aggregate size and fractal dimension (Johnson, Li and

106   Logan 1996; Gregory 1997; Chakraborti *et al.* 2000; Vahedi & Gorczyca 2012), as shown in

107   Equation 4.

108

109   $$v_{st} = \frac{1}{18}\theta g \frac{\rho_p - \rho_w}{\mu} d_{50}^{3-D_f} \frac{d^{D_f-1}}{1+0.15Re^{0.687}} \phi \tag{4}$$

110   where: v_{st} is the settling velocity of an individual floc; g is acceleration due to gravity; μ is dynamic

111   viscosity of water; D_f is the fractal dimension; d is floc size; d_{50} is the median size of particles

112   within floc (i.e. primary particles); θ is a dimensionless particle shape factor; ρ_p and ρ_w are the

113   densities of primary particles and water, respectively.

114     $\phi = \dfrac{m_3}{m_f^{3/D_f}}$ and represents the size distribution of N primary mono-sized particles of diameter d_p in

115   floc, as shown in Equations 5 and 6,

116   where:

117 $$m_3 = \left(\textstyle\sum_{i=1}^{N} d_{p_i}^{\,3}\right)/N \qquad (5)$$

118   and:

119 $$m_f = \left(\textstyle\sum_{i=1}^{N} d_{p_i}^{\,D_f}\right)/N \qquad (6)$$

120   The particle Reynolds, number, is given by Equation 7.

121 $$\mathrm{Re} = \frac{v_{st}d}{v} \qquad (7)$$

122

123   where: v is kinematic viscosity of water.

124

125   Bache et $al.$ (1999) found that the floc effective density (ρ_e), given by $\rho_e = \rho_e - \rho_w$, is related to

126   floc size (d) via Equation 8.

127 $$\rho_e = Ad^{-n} \qquad (8)$$

128

129   where: A is a packing factor and is a function of coagulant dose and coagulation pH; and n is a

130   coefficient that is a function of D_f. For aluminium floc and humic substances, the value of n varies

131   from 1.8 to 2.0.

132   Considering the importance of structural and morphological characteristics of fractal aggregates,

133   the objective of the work reported in this paper is to investigate the porosity and density of

134   aggregates after flocculation based on their fractal dimension calculated individually, measured by

135   a non-intrusive image analysis based method, in order to inform our understanding of floc

136   sedimentation and so improve clarification performance.

137

138   **Methods**

139   **Suspensions**

140   Suspensions were prepared in the laboratory from a kaolinite solution following Yukselen &

141   Gregory (2004) to obtain a turbidity of 25 NTU. The kaolinite was characterized by scanning

142   electron microscopy (SEM) using a JEOL JSM-6010LA microscope coupled to an X-ray

143   spectrometer and via laser granulometry using the Malvern Mastersizer 2000 to obtain composition

144   and mean grain size. The suspension was coagulated with commercial aluminium sulphate, and the

145   pH was adjusted with a 1 M sodium hydroxide solution. The optimum coagulation conditions

146   identified by Oliveira *et al.* (2015) using the same synthetic water were adopted, i.e., 2 mg $Al^{+3}.L^{-}$

147   ^{1}, pH 7.5. Flocculation was performed with mean velocity gradients ($\overline{G_f}$) of 20 - 60 s^{-1}, which

148   were determined by torque measurements, for flocculation times of 15 min to obtain flocs of

149   different sizes and shapes.

150

151   **Data Acquisition**

152   1000 floc images were captured immediately post-flocculation (high-speed Miro EX-4 camera with

153   interchangeable lenses, sampling at 25 Hz for 40 s). Image resolution was 800 x 600 pixels with a

154   visual field of 6 x 8 mm. Shutter speed was set to 800 µs and pixel size was 10 µm. Illumination

155 was via a collimated laser beam modified by a cylindrical lens for plane dispersion with a thickness

156 of 2 mm (following Moruzzi *et al*. 2017) placed perpendicular to the focus direction. Nominal laser

157 power was 2000 mW, producing light at a wavelength of 532 nm (green). A schematic of the

158 experimental apparatus is shown in Figure 1.

159

160 Digital images were processed using Image Pro Plus 7.0 software. The images were transformed

161 into binary matrices by the segmentation process using a degree of 128/256 as the threshold and

162 were then subjected to the particle image velocimeter (PIV) processing of the same package. Area

163 and Diameter (max) of each floc were used to track each aggregate, with cut-off values of 200

164 pixels respectively (Chackraborti *et al.*, 2003). In total, 118 aggregates were selected, for which

165 the attributes of interest (Diameter (max.), Diameter (min.), Diameter (mean), Area, Y coordinate,

166 and Perimeter) were obtained. Further details on data acquisition and treatment can be found in

167 Moruzzi *et al.* (2017, 2019).

168
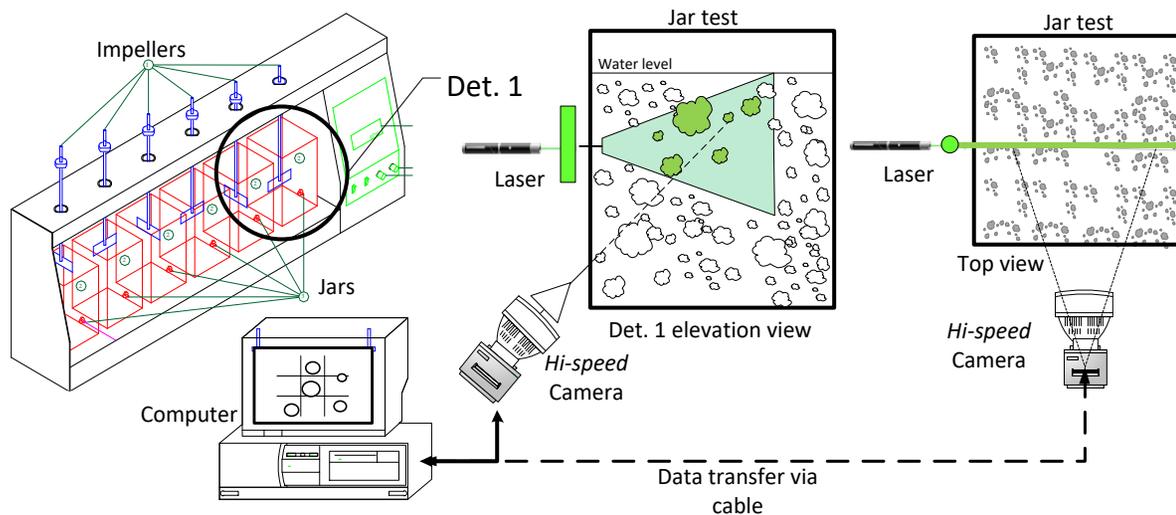

169

170 Figure 1 - Scheme of the experimental apparatus. Adapted from Moruzzi et al. (2017).

171

172 **Determination of fractal characteristics**

173 The value of D_f and the shape parameter, b, for each aggregate can be obtained from linear

174 regression of the experimental data in the linearized form of Equation 9 (i.e. equation 10). Here,

175 the slope of the straight line corresponds to the exponent (D_f) and the intercept corresponds to the

176 shape parameter b.

177 $$N = b \left[\frac{d_f}{d_p} \right]^{D_f} \tag{9}$$

178 $$\ln N = \ln b + D_f \ln \left[\frac{d_f}{d_p} \right] \tag{10}$$

179 where: D_f is the three-dimensional fractal dimension; d_p is the primary particle diameter (m);

180 d_f is the floc diameter (m); N is the number of primary particles of diameter d_p per volume of floc

181 of diameter d_f; b is the shape parameter, defined as:

182 $$b = \left(\frac{\zeta . \xi}{\xi_0} \right)^{D_f/3} \tag{11}$$

183 where: ζ is the packing factor; ξ is the shape factor; ξ_0 is the primary particle shape factor.

184

185 The number of primary particles per unit of aggregate volume, N, was determined by rotation of

186 the ellipsoid about the x-axis of the ellipsoid fitted to the highest and lowest dimensions determined

187 by the image analyses, as illustrated in Figure 2 and Equations 12 and 13, following Chackraborti

188 *et al.* (2000).

189 $$E = \left\{ (x, y, z) \epsilon \mathbb{R}^3 : \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} \leq 1, a > 0, b > 0 \ e \ c > 0 \right\} \tag{12}$$

190 $$V(E) = \iiint_E \left(\frac{\partial A}{\partial x} + \frac{\partial B}{\partial y} + \frac{\partial C}{\partial z} \right) dx . dy . dz = \iint_S z dx dy \tag{13}$$

191 where: A, B, and C are the integration limits of the a, b, and c axes of the ellipsoid (E) with volume

192 V(E); S is the surface of the ellipsoid (E).
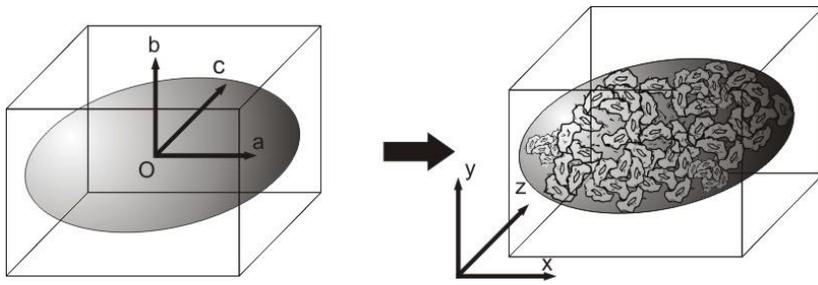

193

194   Figure 2 - Example of aggregate encased in ellipsoid

195   With these data, the value of the three-dimensional fractal dimension (D_{fp}) was obtained for the set

196   of aggregates by fitting the volumes to Equation 14 in the linearized form.

197

198    $V \sim d_{max.}{}^{D_{fp}}$ (14)

199   where: V is the volume of the ellipsoid containing the floc (m^3); $d_{max.}$ is the largest dimension of

200   the floc (m).

201

202   The two-dimensional fractal dimension (D_{fp}') for the set of aggregates was determined using

203   Equation 15, and the ratio of $D_{fp} : D_{fp}'$ for the data set was then used to calculate the three-

204   dimensional fractal dimension per aggregate according to Equation 16. The value of d_p in Equation

205   16 was assumed from kaolin volume distribution, adopting mono-size primary particles as

206   simplification for the D_f calculation.

207    $A \sim d_{max.}{}^{D_{fp'}}$ (15)

208   where: A is the projected floc area on the image plane; $D_{fp}{}'$ is the two-dimensional fractal

209   dimension.

210

211    $D_f = \dfrac{D_{fp}}{D_{fp'}} \left(\dfrac{\ln N}{\ln \left(d_{max}/d_p \right)} \right)$ (16)

212   With the shape, floc dimension, particle dimension, and three-dimensional fractal dimension

213   parameters calculated per particle, the floc porosity and density were determined with Equations

214   17 and 18, considering a mass balance between the floc, the particle, and the voids occupied by the

215   liquid.

216   The porosity of the floc, ε_f, with diameter d_f was determined via:

217

218   $\varepsilon_f = 1 - \left(b.d_f^{D_f-3}.d_p^{3-D_f} \right)$ (17)

219

220   and the floc density, ρ_f , via:

221

222   $\rho_f = \rho_l + \left(b.d_f^{D_f-3}.d_p^{3-D_f}\left(\rho_p - \rho_l \right) \right)$ (18)

223

224   Where: ρ_f is the floc density (kg.m^{-3}); ρ_l is the density of water (kg.m^{-3}); ρ_p is the density of the

225   primary particle (kg.m^{-3}).

226

227   **Settling velocity**

228   The density, floc porosity, and three-dimensional fractal dimension were used to evaluate the

229   sedimentation velocities of Euclidean geometry spheres (V_{sphere}) and fractals ($V_{fractal}$). It was

230   assumed that the floc dimensions did not change during sedimentation. For this purpose, the

231   Newton equation (Equation 19) in equilibrium ($\Sigma F_y=0$) was used for the particular case where the

232   dimensionless Reynolds number (Re) < 1, such that the drag coefficient can be described according

233   to Equation 20. Thus, V_{sphere} can be described by Equation 21 and $V_{fractal}$ by Equation 22, and they

234   distinguish each other in the geometric and density terms of the Equations. The geometric term of

11

235 Equation 22 will always reduce the contribution of size on velocity for fractal aggregates, unless d_f

236 approaches to d_p (for $d_f > d_p$) results in the square relation of Equation 21 (d_f^2). Finally, the ratio of

237 the velocities was determined for each particle according to Equation 23.

238 $$V_{sphere} = \sqrt{\frac{4.(\rho_f - \rho_l).g.d_f}{3.\rho_l.C_d}}$$ (19)

239 where: V_{sphere} is the Newton velocity for the Euclidean sphere (m.s^{-1}); g is the acceleration due to

240 gravity (m.s^{-2}); C_d is the drag coefficient.

241

242 Assuming Re<1,

243

244 $$C_d = \frac{24}{Re} = \frac{24\mu}{V_{st}d_f\rho_l}$$ (20)

245 where: Re is the Reynolds number; V is the floc terminal velocity (m.s^{-1}); μ is the absolute viscosity

246 (N.m^{-2}.s).

247 Hence:

248 $$V_{sphere} = \frac{g(\rho_f-\rho_l)d_f^2}{18\mu}$$ (21)

249 Valid for Re< 1 and $d_f < 1$ mm.

250

251 $$V_{fractal} = \frac{g(\rho_p-\rho_l)d_f^{D_f-1}d_p^{3-D_f}.b}{18\mu}$$ (22)

252 where: $V_{fractal}$ is the velocity based on fractal aggregates with diameter d_f (m.s^{-1}).

253

254 The dimensionless quotient of the fractal and Euclidean sphere velocities, Γ, is defined as:

255 $$\Gamma = \frac{V_{fractal}}{V_{sphere}}$$ (23)

12

Results and discussion

Figure 3 shows the kaolinite (Kaolin, Fluka) particle size distribution: 0.4 – 100 μm, in volume

with median 7.5 μm and in number (N) with median 1.0 μm, which is in agreement with other

studies (Zbik & Smart 1998, Aparicio *et al.* 2004). An example of one scanning electron

microscopy image taken from the kaolin dry sample is also presented in detail, showing

qualitatively the range of size, shapes and textures of the primary particles. This result supports

the definition of the appropriate pixel size for the determination of the smaller cluster of the

aggregate, and primary particle size adopted herein as well.

Figure 4 shows a post flocculation ($G_f = 20$ s^{-1}, $T_f = 15$ min) aggregate characterization image. It is

clear that any assumption of solid sphericity, and hence use of traditional Stokes' law approach is

inappropriate for representing the shape of aggregates. Further, the existence of voids within the

floc alters the porosity and density of the aggregate, both of which affect floc terminal velocity.
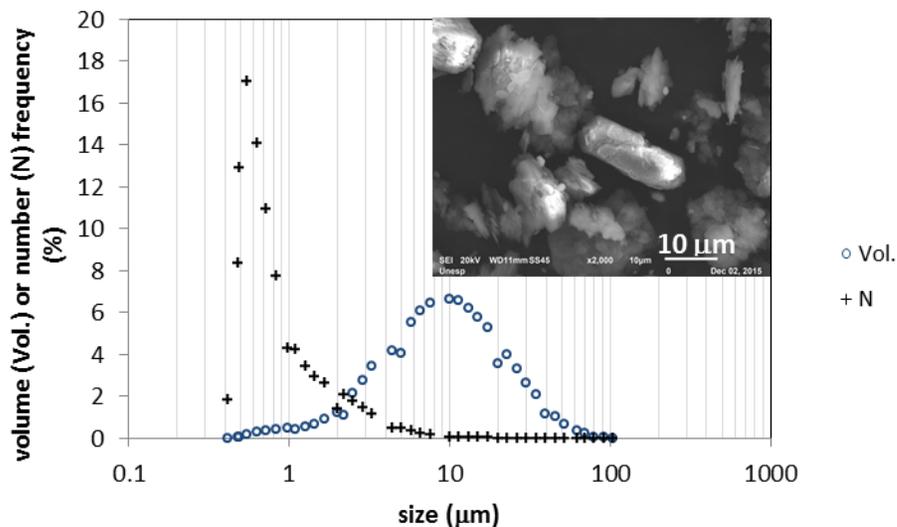

Figure 3 - Kaolin size distribution in number and volume. Scanning electron microscopy (SEM)

image detail in the right upper side.

272

273   Figure 4 - Example of a porous aggregate image taken during sedimentation.

274

275   Figure 5 shows the relationship between log volume of the encased ellipsoid and the log of the ratio

276   of d_{max}:d_p, from which the values $b = 0.78$ and $D_{fp} = 2.35$ were determined (Equation 10). The

277   value of D_{fp} represents elongated medium aggregates, far from a perfect sphere, and agrees with

278   other studies (Johnson, Li and Logan 1996; Chackraborti *et al.* 2003; Li *et al.* 2006). Plotting log

279   aggregate area against log (d_{max}/d_p) yielded a 2-d fractal dimension, D_{fp}', value of 1.50. (Figure

280   S.I.1).
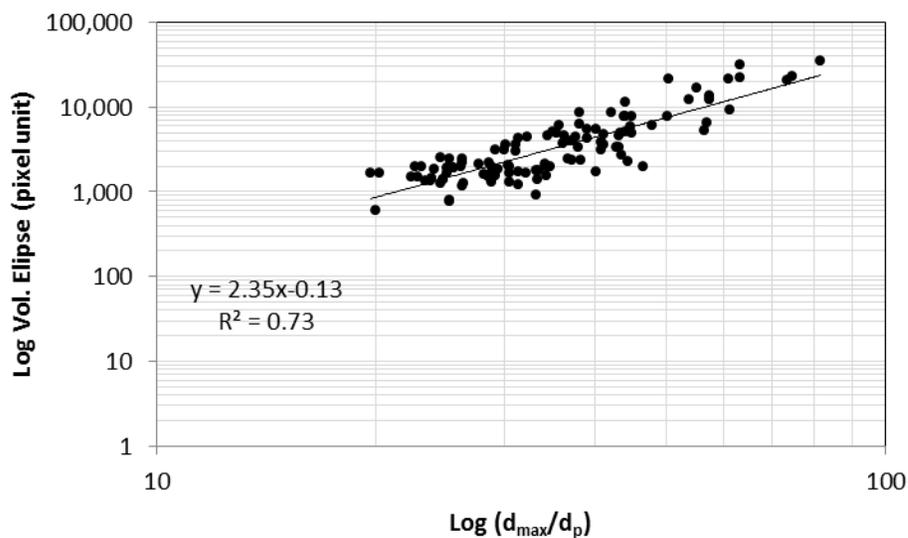

281

282   Figure 5 – Determination of three-dimensional fractal dimension from image analysis

283   measurements by means of *log-log* plot of volume versus relative longest length based on pixel

284   size.

14

285   These results were then applied to Equations 16, 17, and 18 to determine the three-dimensional

286   fractal dimension, porosity and density for the flocs.

287

288   Table 1 presents descriptive statistics obtained from all the aggregates in terms of the highest

289   dimension ($D_{max.}$), lowest dimension ($D_{min.}$), mean dimension (D_{mean}), aggregate fractal dimension

290   (D_f), porosity (ε), sphericity (Ψ) and density (ρ). Results show that the mean of the flocs' highest

291   dimension (D_{max}) was 362 μm, with a maximum of 816 μm, a standard deviation of 121 μm, and a

292   confidence interval (0.05) of 21 μm. For the flocs' lowest dimension (D_{min}), a mean of 138 μm

293   was obtained, with a maximum of 310 μm, a standard deviation of 47 μm, and a confidence interval

294   for the mean (0.05) of 8 μm. The average floc size obtained in the experiments was 231 μm, with

295   a maximum of 451 μm, a standard deviation of 70 μm, and a confidence interval for the mean

296   (0.05) of 12 μm. The three-dimensional fractal dimension (D_f) calculated per aggregate has a mean

297   of 2.61 for the interval [2.33 to 2.83], indicating a variety of floc shapes, ranging from the most

298   elongated to those close to spheres, in the limits of the interval. For the experiments, density was

299   obtained for the flocs (ρ_{floc}) with a mean of 1068 kg.m^{-3} within the range of [1024 to 1138 kg.m^{-3}].

300   The mean porosity (ε) of the aggregates was 0.76 with an interval of [0.53 to 0.91]. Sphericity (Ψ)

301   and aspect ratio (D_{max} / D_{min}) of 0.58 and 2.62 average, respectively, have shown that flocs are

302   majority elongated structures, far from spherical.

303   Figure 6 shows the relationship between porosity and fractal dimension, with the more open

304   structures (D_f<2.5) having a greater porosity (>80%) than more closed structures. To a lesser extent

305   than shape, large size flocs have also shown greater porosity for the same fractal dimension. The

306   average porosity found here (approximately 76%) is in agreement with Gorczyca & Ganczarczyk

307   (1999) and Vahedi & Gorczyca (2012) for large flocs. There is no doubt that shape and porosity

308 are dependant floc traits which may affect settling rate, however the nonhomogeneous mass

309 distribution and pore population within aggregate structure are also important for terminal velocity,

310 and should be considered for further developments, as suggested by Vahedi & Gorczyca (2014).

311

312 Table 1 – Descriptive statistic for aggregates' highest dimension ($D_{max.}$), lowest dimension ($D_{min.}$),

313 mean dimension (D_{mean}), fractal dimension (D_f), porosity (ε), sphericity (Ψ), aspect ratio (D_{max} /

314 D_{min}) and density (ρ).

Attribute	Average	Standard Deviation	Max	Min	95%*
D_{max} (µm)	362	121	816	196	21

316

317 The direct consequence of the shape and porosity relation on flocs settling rates is the influences

318 on an aggregate's density and drag. Unless water can flow through flocs voids, reducing resistance

319 to settle, an elongated aggregate is more likely to have lower settling rates than those ones closer

320 to a sphere-shape. The so called flow-through effect is still not well understood and there is also

321 no consensus on the contribution of permeability for terminal velocities of porous aggregates.

322   Whilst initially Adler (1983) showed that the effect of permeability on flocs settling is minor and

323   that is unlikely water can flow through pores during sedimentation. Nevertheless, Johnson et al.

324   (1996) showed the more porous the floc is, the more likely fluid can flow through it, increasing

325   permeability and so reducing resistance to settle. In general, literature has shown that elongated

326   aggregates are likely to settle at lower rates than spheres and, according to Bushell et al. (2002), it

327   is difficult to explain the greatly reduced resistance to settle described by Johnson et al. (1996).

328

329   Figure 7 shows that more spherical; less elongated aggregates (with increased D_f values) display a

330   greater density, contributing to higher terminal velocity of aggregates. Therefore, the density of the

331   aggregates varies inversely with porosity. If the mass was the predominant effect on floc settling

332   velocity, compact spheres would always exhibit higher settling velocities. In fact, several

333   researchers have shown that fractal aggregates can settle with slower velocities than those predicted

334   by Stoke's law (Vahedi & Gorczyca, 2012; Tambo, 1979; Khelifa & Hill, 2006; Jarvis, et al., 2008).

335   Consequently, terminal velocities of aggregates will mostly depend upon the dual effect of porosity

336   and density, determined to a great extent by aggregate shape, i.e fractal dimension.

337   Based on the experimental results, it was possible to construct a relationship between porosity (ε)

338   and the density (ρ_f) of the aggregate (S.I. Figure 2, and Equations 24 and 25) such that:

339    $\varepsilon = A(1 - B\rho_f)$ (24)

340   where:

341    $A = \left(1 - \dfrac{\rho_l}{\rho_p}\right)^{-1}$ (25)
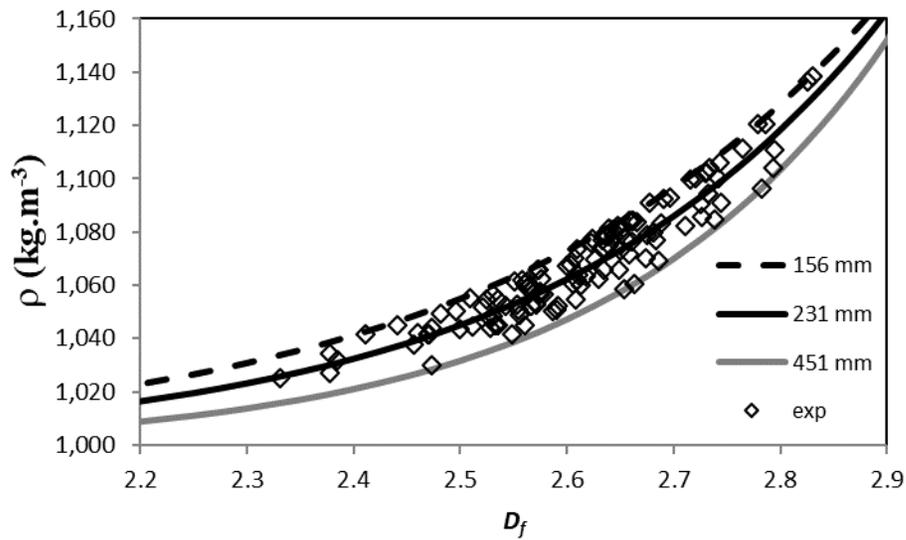

342    $B = {\rho_p}^{-1}$

343

344

Figure 6 –Aggregates porosity ε (−) as a function of D_f for the minimum, average and maximum

aggregate size in micrometer (μm).

347

348

Figure 7 – Density of the aggregates ρ_f as a function of D_f for the minimum, average and maximum

aggregate size in micrometer (μm).

351

352 Common practice for designers of sedimentation tanks is to adopt average floc density for perfect

353 spheres, so that settling velocities of aggregates can be simulated using a characteristic aggregate

354 size and Stokes's law, as Equation 21. However, results shown here suggest that flocs are

355 elongated, porous structures, and far from spherical.

356

357 The impact of this oversimplification of floc shape is that the drag force changes as result of the

358 cross-section area, thus altering the settling velocity. In general, it is supposed that deviation from

359 sphericity will result in increasing drag, irrespective of floc orientation and permeability (Bushell

360 et al., 2002). However, Johnson et al. (1996) suggest that the actual drag is lower than that

361 calculated for fractal aggregates, even when permeability is considered. Figure 8 shows calculated

362 settling velocity for spheres and flocs (based on Equations 21 and 22 for d_p of 7.5 µm, this being

363 median particle size by volume) against floc size for different shapes, i.e. fractal dimensions ($D_f =$

364 3.00 for spheres; 2.33, 2.61 and 2.83 for fractals).

365

366 Figure 8 shows that fractal aggregates of size between 100 and 300 µm settle with velocities

367 between 0.3 and 7.9 mm/s, which is in agreement with results presented by Vahedi & Gorczyca

368 (2012), Khelifa & Hill (2006) and Jarvis *et al*. (2008), who performed both experiments and

369 simulations. The authors showed settling velocities varying from 0.1 to 7.1 mm/s for aggregate size

370 between 100 and 300 µm, corroborating that the simulations presented here are within experimental

371 measurements performed by several authors. Nevertheless, results compiled by Khelifa & Hill

372 (2006) reveal there is considerable scatter in settling velocity of fractal aggregates, varying up to

373 100 fold each other for the same floc size, possibly due to the nonhomogeneous mass distribution

374 and pore population mentioned by Vahedi & Gorczyca (2014). Here, aggregates with a fractal

375   dimension of 2.83 settled with higher velocities than spheres of same size, for all range of floc

376   sizes, due to the usual assumption that spherical flocs have the same density as fractal aggregates,

377   and so less mass than aggregates of equal size.

378

379   Conversely, for aggregates with fractal dimension of 2.33 and 2.61 there is a size threshold above

380   which fractals settle with lower velocities than those calculated using Stokes' law for compact

381   spheres. For small floc sizes, close to the size of primary particle ($d_f \approx d_p$), the geometric term of

382   Equation 22 approaches to the term d_f^2 from Equation 21 and, therefore, the differential density

383   between particle and liquid is the predominant driving effect over settling rate, surpassing the

384   reduction caused by the fractal geometry. However, the differential density is not enough to surpass

385   the reduction in the geometry term of Equation 22, caused by the low fractal dimension of elongated

386   large aggregates. Results presented by Vahedi & Gorczyca (2012) have also shown that multi

387   fractal aggregates can settle with lower velocities than those predicted by modified Stokes' law, by

388   introducing a porous effect into the original equation. The authors simulated fractal aggregates with

389   multi fractal dimension varying from 2.6 to 2.7 and aggregates size less than 320 μm. In contrast,

390   experiments carried out by Johnson *et al.* (1996) showed that settling velocities of fractal

391   aggregates were between 4 and 8 times greater than those predicted by Stokes' law, for aggregates

392   size in the range of 100 to 1000 μm. Here, fractal aggregates ($D_f = 2.61$, $d_f > 320$ μm) settle with

393   lower velocities than those predicted by Stokes' law; whilst, for $D_f = 2.33$, all aggregates of $d_f > 70$

394   μm and $d_p = 7.5$ μm settled below the velocity calculated by Stokes' law for spheres.

395

396   The ratio of the fractal to Euclidean velocities (Γ) is shown in Figure 9-a for different values of the

397   aggregates' mean equivalent diameter (d_f) in the situation ($D_f = 3.00$ for spheres; 2.33, 2.61 and

398   2.83 for fractals). The ratio of fractal aggregate to sphere settling velocity (the former being

399   obtained from fractal porosity and density considerations), varied from 0.16 to 4.11 for aggregates

400   in the range of 10 and 1000 μm, primary particle size of 7.5 μm and three-dimensional fractal

401   dimension between 2.33 and 2.83. This emphasizes that fractal aggregates can behave differently,

402   settling with higher or lower velocities, compared to Stokes' law, once settling velocities of

403   aggregates depend upon the dual effect of porosity and density, determined by the aggregate's

404   shape. Although large elongated flocs contain higher mass their shape results in lower contribution

405   of geometric term of Equation 22 over settling rate than small flocs. This would only be overcome

406   whether water could flow through flocs' pores whilst settling, as a result of macro pores distribution

407   within aggregates, as mentioned by Vahedi & Gorczyca (2012). Again, there is no consensus about

408   the permeability effect on settling rate of fractal aggregates, and despite the fact that permeability

409   was not considered here for modelling, the findings are in agreement with a wide range of

410   experiments, like those performed by Vahedi & Gorczyca (2012) and Johnson, Li and Logan

411   (1996), for instance.

412

413   On the other hand, if primary particle size is changed, results vary for the same fractal geometry.

414   Figure 9-b shows the effect of primary particle size (d_p) on Γ. Results were taken following the

415   same procedures used for Figure 9-a, and it is clear that the d_p of 1.0 μm can change the ratio of

416   fractal aggregate to sphere settling velocity markedly to values between 0.04 to 2.92, i.e. in a lower

417   range when compared to d_p of 7.5 μm. For the same fractal dimension, the lower d_p the higher the

418   porosity and, therefore, the lower the density thus affecting the mass contribution over terminal

419   velocities of aggregates. Further, results showed all velocities simulated for fractal dimension of

420   2.33 were far lower than those predicted by Stokes' law for spheres ($\Gamma < 1$), and only aggregates

421   with size lower than 40 μm settled with higher velocities than Stokes' law for spheres when fractal

422   dimension of 2.61 was simulated; although, Γ was always higher than 1 for fractal dimension of

423   2.83.

424

425   Whether lower or higher, simulations have shown that settling velocities of fractal aggregates can

426   be far different from those predicted by spheres using Stokes' law. The factors affecting settling

427   velocities of fractal aggregates depend upon size, shape, porosity, permeability, primary particle

428   size, and are far more complex than assumed by Stokes' law for spheres. Results presented in this

429   paper have shown that settling velocities may vary strongly when floc shape changes from spherical

430   to fractal aggregates, and the accuracy of predictions varies with floc size, fractal dimension and

431   primary particle size. In practice, settling velocities of flocs are a function of floc size and fractal

432   dimension, which are controlled by coagulation flocculation units.

440

441   **Conclusions**

442   In this study, the porosity and density of aggregates formed after the flocculation of water

443   containing kaolin were calculated using fractal dimension, and the terminal velocities of the

444   Euclidean sphere and of the fractal aggregates were determined using images of a series of 118

445   flocs measured individually.

446

447   Settling has not been used as a means to characterise aggregates behaviour, but image analysis

448   instead. Therefore, simulations here performed derived from aggregates' characteristics taken by

449   image analysis, to input data into both the Stokes' equation and the modified equation, based on

450   fractal geometry. Findings are in agreement with a wide range of aggregates traits and setting rates

451   reported in literature, confirming that results are reliable.

452

453   A consistent increase of aggregate porosity with decrease of fractal dimension was observed, and

454   the opposite was observed for density of aggregates. Therefore, more spherical aggregates display

455   a greater density, contributing to higher terminal velocity of aggregates.

456

457   It was found that fractal aggregates can behave differently, settling with higher or lower velocities,

458   compared to Stokes' law, once settling rates of aggregates depend upon the dual effect of porosity

459   and density, determined by the aggregate's size and shape. For small floc sizes, close to the size of

460   primary particle ($d_f \approx d_p$) the differential density between particle and liquid is the dominant effect

461   on settling rate, surpassing the geometry reduction yielded by fractal aggregates. The opposite was

462   observed to large fractal aggregates, where the differential density was not big enough to surpass

463   the reduction caused by the low fractal dimension of elongated aggregates.

464

465   The results obtained differ from other work in the field by calculating settling velocities from fractal

466   dimension and demonstrated the importance of advancing the analysis of particles considering their

467 sizes and shapes beyond those described by Euclidean geometry. Specifically, applying fractal

468 geometry to determine the porosity and density of the flocs is an important evaluation tool, with

469 far-reaching implications for sedimentation tank design and operation.
